³Field Science Center for Northern Biosphere, Hokkaido University, Sapporo 060-0809, Japan

Morphological, molecular and chromosomal studies were carried out on *Tauya basicrassa*, an endemic kelp species distributed on the northern continental coast of the Sea of Okhotsk in Russia. The sporophytes of *T. basicrassa* grow up to 3-6 m long, 1.8-2.2 m wide, and 6.5-7 kg wet weight. The thallus has a blade with very thick narrow basal portion and thinner and much broader upper portion, which usually splits into 3 bullated lobes. A dwarf laminariacean alga, which did not show any morphological similarity to the other species of the order Laminariales, was found from the same locality. The blade of this alga is thin and soft, reached 26-34 cm long and 6-6.5 cm wide and had 4 longitudinal rows of bullations that covered the entire blade. Molecular analysis showed that the dwarf alga has 100% sequence identity in plastid-encoded RuBisCo spacer, mitochondrial cytochrome c oxidase subunit 1 and nuclear-encoded rDNA genes with normal sporophytes of *T. basicrassa*, indicating that they are different life forms of the same species. Fluorescent DAPI staining showed that the nucleus in the normal sporophyte was 50-65% larger than those of the dwarf ones. Chromosome count using acetocarmine staining showed $n = ca. 20$ for the normal sporophytes of *T. basicrassa* and $n = ca. 10$ for the dwarf one. These results suggest that the dwarf thallus is a haploid parthenosporophyte of *T. basicrassa*, which developed in nature. This is the first evidence of parthenosporophytes of the laminariacean algae occurring naturally in the field.

Key Words: chromosome; endemic kelp; Laminariales; molecular phylogeny; morphology; parthenosporophyte; Sea of Okhotsk; *Tauya basicrassa*

INTRODUCTION

The brown algae belonging to kelp species are one of the most intensively studied seaweeds due to their wide commercial application and consumption as food and medicine. It was believed that the generic composition of kelp in the world ocean was established by the end of last century (Wynne 1982), therefore new discovery of the endemic genus, *Tauya* Klochkova et Krupnova from

Russia containing a single species, *T. basicrassa*, was unexpected and exciting (Klochkova and Krupnova 2004). The genus *Tauya* was described from Tauy Bay (Russian: Tauyskaya Guba) located on the northern continental coast of the Sea of Okhotsk. This remote and sparsely populated northern area has harsh, almost Arctic climate (Klochkova et al. 2010, 2012, 2013), but at the same time

it is the most phycologically well-studied area in the Sea of Okhotsk. It was therefore surprising that the giant kelp species such as *Tauya* was overlooked until 2004 (Klochkova and Belij 2006).

Nowadays, the systematics of kelp genera and species is based on the DNA analysis, rather than on morphology and anatomy (Cho et al. 2006, Lane et al. 2006, Boo et al. 2011). The morphological characteristics of genera often contradicted to the results of genetic analysis, and traditionally used taxonomic key characters became somewhat obsolete in case of kelp. As the description of *T. basicrassa* was based on morphology and anatomy without any molecular-phylogenetic analysis, it has been regarded as Laminariales familia incertae sedis (uncertain family) (Guiry and Guiry 2016).

During hydrobiological expedition held in July 2008 we found an unusual small kelp species at the depth of 7 m in Svetlaya bay, which is located inside Taui Bay. It had several morphological characters clearly distinguishable from other described kelp species from the Sea of Okhotsk and any kelp genus known to date. While analyzing our underwater videos of seaweed beds, it became apparent that such unusual plants were very rarely distributed in other areas of Taui Bay. First information about this species was published in Klochkova and Belij (2010) and later in the book on seaweed flora of the northern coast of the Sea of Okhotsk (Klochkova et al. 2013). We preliminarily applied the name *Laminaria* sp. and called it “bullate small kelp” until further genetic information is available (Klochkova et al. 2013).

In this paper, we present first molecular-phylogenetic analysis of *T. basicrassa* and “bullate small kelp” based on the plastid-encoded RuBisCo spacer, mitochondrial cyto-

chrome c oxidase subunit 1 (COI) and nuclear-encoded rDNA sequences. Unexpectedly, they turn out to be genetically identical, indicating that they are different life forms of the same species. Ploidy levels of both morphotypes were analyzed using fluorescent DAPI staining and chromosome counting.

MATERIALS AND METHODS

Sample collection and specimen observation

Samples of *Tauya basicrassa* were collected with SCUBA diving and also cast ashore during hydrobiological expedition held in July 2008 on the northern continental coast of the Sea of Okhotsk (Belij 2013, Klochkova et al. 2013). Collection sites inside Taui Bay included Nedorazumeniya Island (type locality) and Svetlaya bay (Fig. 1). We also re-investigated type specimen (Fig. 2A & B) currently preserved in Kamchatka State Technical University (type information: Russia, Sea of Okhotsk, Taui Bay, Nedorazumeniya Island, depth 15 m, coll. on Jul 16, 2000, by T. N. Krupnova). It should be noted that the type specimen is in a fragile condition, because unlike other kelp specimens, large thin blades of *T. basicrassa* are very fragile when dried and they crack and crumble easily. We also studied another specimen of *T. basicrassa* collected in June 1975 from Taui Bay by L. Prudnikova, provided for our herbarium collection by TINRO-center (Vladivostok, Russia) (Fig. 2C). For the estimation of plant age, we counted the number of annual rings on the cross-section of stipes and analyzed overall plant morphology (Klochkova et al. 2012). For microscopic observations, small

Fig. 2. Sporophytic plants of *Tauya basicrassa* from the Sea of Okhotsk. (A) Drawing of the authentic specimen showing a deep-water plant with large undissected blade with several longitudinal clefts (Nedorazumeniya Island). (B) Drawing of holotype specimen collected from the upper sub-tidal zone (reproduced with permission from Klochkova and Krupnova 2004). (C) Dry specimen collected by L. Prudnikova on June 1975 from Taiu Bay (Sea of Okhotsk). In herbarium specimens, the basal part of blade becomes much darker. (D & E) Dorsal and ventral sides of the basal part of same blade, showing a concave-convolute hood-like structure with bullations. Three distinct portions are marked with numerals. Scale bars represent: A, 50 cm; B, 4 cm; C, 7 cm; D & E, 2 cm.

pieces of plants were incised from different parts of the blades. They were rehydrated in sterilized seawater, cut with a fine razor blade, and observed under a light microscope. Micrographs were taken with Olympus DP50 digital camera affixed to an Olympus BX50 microscope (Olympus, Tokyo, Japan) using Viewfinder Lite and Studio Lite computer programs (Better Light Inc., Placerville, CA, USA).

Molecular identification and phylogenetic analysis

For extraction of genomic DNA, pieces of plants incised from different parts of the blades were rehydrated in sterilized seawater and their surface was thoroughly cleaned with a fine brush. They were transferred to 2.0-mL cryotubes and frozen in liquid nitrogen. The best results were obtained when tissue for DNA extraction was obtained from the basal part of blade. The cryotubes containing pieces of plants were shaken at 5,000 rev min⁻¹ for 2 min with a cell homogenization machine. The DNA was then extracted using an Invisorb Spin Plant Mini Kit (Invitex, Berlin-Buch, Germany) with some modifications of the manufacturer's protocol that we applied in case of extracting DNA from the kelp samples. The plastid-encoded RuBisCo spacer was amplified using primer sets RS1-RS2, KR3-KR4, nuclear-encoded rDNA was amplified with the primer sets LB1-BC2 (ITS1 region) and YB1-LB2 (ITS2 region), and mitochondrial COI gene was amplified using the primer set GazF2-GazR2 (Saunders and Druehl 1993, Yoon and Boo 1999, Yoon et al. 2001, Lane et al. 2006, 2007). TaKaRa Ex Taq polymerase (Takara Biomedicals, Otsu, Japan) was used for the PCR amplifications. The following PCR program was used: initial denaturation at 95°C for 4 min, followed by 35 cycles of denaturation at 94°C for 30 s, annealing at 55°C for 30 s, extension at 72°C for 1.5 min and a final extension at 72°C for 10 min. PCR products were checked on an agarose gel for length, concentration, and purity. Sequencing was performed commercially (Cosmogenetech Co., Ltd., Seoul, Korea). On the total, we sequenced 981 nt for rDNA regions in both samples (18S rRNA, ITS1, 5.8S rRNA, ITS2, and 26S rRNA). For RuBisCo spacer, 633 nt were sequenced including partial *rbcL* and *rbcS*, and for COI gene, 396 nt were sequenced.

Our new sequences and sequences from GenBank (National Center for Biotechnology Information 2016) were aligned using Geneious (ver. 7.1.8; Biomatters, Auckland, New Zealand) and the alignments were refined by eye. For rDNA alignment, our sequences were trimmed up to 619 nt to match the alignment length of other sequences

from the NCBI; total alignment was 744 nt-long with 125 indels/gaps. RuBisCo alignment was 653 nt-long with 20 indels/gaps. The trees were generated using Bayesian phylogenetic analysis (MrBayes 3.2.2) (Huelsenbeck and Ronquist 2001) using a GTR substitution model, 3,000,000 generations, sub-sampled every 1,000 generations and a burn-in length of 300,000 generations. Maximum likelihood analysis used RAXML 7.2.8 (Stamatakis 2014) using a GTR + gamma model. Bootstrap support values (%) were calculated based on 500 bootstrap replicates. Our new sequences have been deposited in GenBank under the following accession numbers: KY434160 (rDNA, normal sporophyte), KY434161 (rDNA, parthenosporophyte), KY434162 (RuBisCo, normal sporophyte), KY434163 (RuBisCo, parthenosporophyte), KY434164 (COI, normal sporophyte), KY434165 (COI, parthenosporophyte).

Nuclei staining and chromosome observation

For nuclei staining, 1 mg mL⁻¹ stock solution of DAPI (4',6-diamidino-2-phenylindole; Sigma, St. Louis, MO, USA) dissolved in distilled water was applied to the cross-sectioned materials incised from different parts of the blades at a concentration of 5 µg mL⁻¹ for 5 to 10 min and heated in a microwave for a few seconds. The stained nuclei were examined under a UV filter. In both types of plants (large and dwarf blades), the nuclei were marked and their areas were compared. On the total, we measured 20 nuclei in each type of plant and compared their surface areas. For observation of chromosomes, aceto-carmin solution (carmin 2 g, glacial acetic acid 45 mL, ddH₂O 50 mL) was prepared by boiling for 2-3 h and filtering through several layers of the filter paper. For chromosome staining, 2-3 drops of aceto-carmin solution were applied to the rehydrated and cross-sectioned tissue taken from the meristem zone. Fine sections were put on a slide glass and covered with a cover slip, and heated over the boiler for 1-2 min. Thereafter, the sections were strongly squashed between the slide glass and the cover slip. Chromosomes thus stained were examined with Olympus BX50 microscope while still immersed in the stain. On the total, we marked and counted chromosomes in 7 and 10 nuclei of the large (i.e., normal sporophytes) and dwarf (i.e., parthenosporophytes) plants of *T. basicrassa*, respectively. Because the chromosomes spread out in three dimensions, the numbers were counted by tracing and marking individual chromosomes through stacks of consecutively taken images (Mann and Pouličková 2010). First, the labeling was accomplished for all nuclei in both types of plants and then counting was performed.

RESULTS

Morphology and anatomy, ecology and distribution

Tauya basicrassa (normal sporophytes). Large sporophytic plants have unique morphology of blade (Table 1, Figs 2A-C & 3A); it is very wide, entire or bearing longitudinal clefts in young plants and dissected into 3 or more lobes with age. In fresh plants extracted from the sea, the blades' basal part is narrow, thick, cartilaginous and lighter in color than the rest of the blade (Fig. 3A & B), looking like a concave-convolute hood with bullations (Fig. 2D & E). On the contrary, in dried plants the basal part becomes much darker, whereas the upper part becomes lighter (Fig. 2C). The blade's upper part bears 8-9 rows of bullations, is very fragile and crumbles easily, so that only the rigid basal part with stipe remains (Fig. 2D & E). Stipe is very short, flattened in its upper portion; haptera are rigid, thick and branched (Fig. 3B). In adult plants, the blade's thickness is 1,300-1,360 μm in the basal part and 345-352 μm in the upper part; the medullar layer is 141 and 64 μm thick in the basal and upper parts, respectively. Cortex is 12.8 μm thick and consists of one layer of pigmented isodiametric cells; beneath the cortex layer very large thick-walled cells are distributed.

Development of bullations begins in the juvenile plants (Fig. 3C & D). On the blade, bullations are localized between smooth and more thickened ribbon-like stripes; the mature plants usually have 6 of such stripes. Sizes of bullations become gradually larger according to the increase of the blade's width. During the reproductive period occurring from August to early September, sporangial sori begin to develop on these ribbon-like stripes (Fig. 3E), and later the sori spread outside the stripes.

In *T. basicrassa*, morphological differentiation of thalli begins early in plants' development (Fig. 3C & D). Although its anatomy is similar to other laminariacean algae, it has some specific characters such as glandular cells (Fig. 3F) and large mucilage ducts up to 77-128 μm in size in the cross-section (Fig. 3G & H), which spread on the whole basal part and meristem zone of the blade. The mucilage ducts form a conductive system in the tissue (network of channels), which acts as an elastic armature, reinforcing the blade on its surface. The mucilage ducts are absent in the upper part of blade.

In Taiu Bay, *T. basicrassa* inhabits lower border of the phytal zone and is found in places with lower level of

hydrodynamics, at depths of 4-22 m, on rocky substrate covered with sand and silt. It has preference for the cold-water bottom layer of the seawater stratum, forming mono-species communities with an average biomass up to 7.5 kg m^{-2} or growing in groups in mixed communities among other laminariacean algae. Under favorable conditions, the largest plants reach 3-6 m long, 1.8-2.2 m wide, and 6.5-7 kg in wet weight.

Our survey on the continental coast of the Sea of Okhotsk revealed that *T. basicrassa* has a broader distribution than previously thought and grows not only in Taiu Bay, but in the proximate more southern and northern regions. However, the gigantic plants develop only in the type locality, i.e., in the area close to Nedorazumeniya Island, because of special bottom relief and increased levels of nutrients in this place, which induce an unlimited growth of plants. The plants have smaller sizes not exceeding 1-1.5 m at length in places with high waves at depths of 5-8 m. In some coastal areas, *T. basicrassa* occupies the sub-tidal fringe, becoming stubby and not exceeding 45-65 cm at length. As estimated from studying the morphology of plants and characteristic annual rings on the cross-section of stipes, *T. basicrassa* can live for no less than 4 years.

Tauya basicrassa (parthenosporophytes). Thallus of this small yellowish-brown kelp has a small holdfast with weakly branched haptera, 1.7 cm-long stipe and a thin, soft, bullate blade reaching 26-34 cm long and 6-6.5 cm wide. Sculptured bullations are arranged into 4 longitudinal rows, covering the entire blade, forming very distinct longitudinal as well as transverse rows (Fig. 4A & B). The margins of blade are mostly strait, with several large folds in the upper portion. On overall, blades are thin (up to 102 and 86-99 μm in the basal and upper portions, respectively), becoming slightly thicker towards the edges (Fig. 4D & E); cortex is 9.6 μm thick, composed of one layer of pigmented isodiametric cells, covered with an entire thickened mucilaginous covering on the outer surface (Fig. 4F & G). Meristoderm is composed of 2-3 layers of large thick-walled cells. Medullar is weakly developed, almost absent. As seen in cross-sections, some cells are filled with brown-red content (Fig. 4D-F). In fresh plants extracted from the sea, the basal part of blade is not different in color than the rest of the blade (Fig. 4B), whereas in dried plants the basal part becomes much darker (lower 1/4 of blade) than the upper part (Fig. 4C). Only sterile plants were collected. As estimated from studying their morphology, these plants were at least 1 year old.

Fig. 3. The morphology and anatomy of normal sporophytes of *Tauya basicrassa* from the Sea of Okhotsk. (A) Mature plant freshly extracted from the sea. (B) Stipe is short and flattened in the upper portion, and haptera are rigid and branched as seen on the cross-section. (C & D) Juvenile plants at different state of maturity, showing two (C) and four (D) rows of developing bullations. (E) Sporangial sori in mature plants (arrows, reproduced from Klochkova et al. 2013). (F) Cross-section of blade in the thickened basal part, showing glandular cells (dashed arrows) and large mucilage ducts (solid arrows). (G) Tangential longitudinal section showing conductive system formed with mucilage ducts, which look similar to a network of channels (solid arrow). Numerous glandular cells can be seen (dashed arrow). (H) Cross-section of mucilage duct. Scale bars represent: A & E, 10 cm; B-D, 5 cm; F, 500 μ m; G, 200 μ m; H, 100 μ m.

Fig. 5. Bayesian inference of phylogenies of the brown algae belonging to kelp species based on plastid-encoded RuBisCo spacer sequences. Labels on branches are posterior probabilities (>75) and consensus support values. Our new sequences are shown with arrow.

Molecular identification

Phylogenetic analysis using plastid-encoded RuBisCo spacer, rDNA and COI showed that the giant sporophytes of *T. basicrassa* and bullate small kelp were identical (Figs 5-7). In each tree, they formed a separate well-supported clade and did not fall into any known algal genus sequenced to date. In RuBisCo tree, the “*Tauya*” clade positioned between the clade formed by five different species from Lessoniaceae and *Cymathaere triplicata* (Postels et Ruprecht) Agardh from Laminariaceae. In rDNA and COI trees, *Tauya* belonged to the family Laminariaceae.

Nuclei staining and chromosome observation

Fluorescent DAPI staining showed that the volume of nuclei in the normal sporophytes of *T. basicrassa* was by 50-65% larger than in the parthenosporophytes (Fig. 8A & B). Chromosomes from the cells in meristem zone of both plants stained with acetocarmine were observed. It was quite difficult to examine the exact shape of chromosomes, as the thick cell walls prevented use of the normal “squash preparation” methods. The shape was dot-like or slightly elongated in both species, sizes were identical, and the numbers were $n = ca. 20$ in *T. basicrassa* normal sporophyte and $n = ca. 10$ in the parthenosporophyte (Fig. 8C-E).

Fig. 6. Bayesian inference of phylogenies of the brown algae belonging to kelp species based on rDNA regions sequences (18S rRNA, ITS1, 5.8S rRNA, ITS2, 26S rRNA). Labels on branches are posterior probabilities (>75) and consensus support values. Our new sequences are shown with arrow.

Fig. 7. Bayesian inference of phylogenies of the brown algae belonging to kelp species based on cytochrome c oxidase subunit 1 (COI) sequences. Labels on branches are posterior probabilities and consensus support values. Our new sequences are shown with arrow.

(D & E) Selected through-focus images of chromosomes in the small nuclei of parthenosporophytes and chromosome counting. Scale bars represent: A-E, 5 μ m.

DISCUSSION

Morphological characteristics of the genus *Tauya* are clearly different from other laminariacean species (Klochkova and Krupnova 2004), but it has long been treated as Laminariales familia incertae sedis (uncertain family) because there has been no molecular data supporting the establishment of the genus (Guiry and Guiry 2016). Our molecular analysis based on rDNA and COI genes suggested attribution of *Tauya* to the family Laminariaceae, which is also in agreement with morphological characters of this genus.

T. basicrassa was originally described as an endangered endemic species with very narrow distribution on a small area of sea bottom characterized by specific hydrological conditions (Klochkova and Krupnova 2004). The type lo-

cality of *T. basicrassa* was the small area on the sea bottom located inside Taui Bay between Nedorazumeniya Island and continental coast (mainland). This area not exceeding 1/3 of a square kilometer looks like a deep trench in the sea, with a substrate made with rocks, pebbles and sand. Because of such peculiar bottom relief, large depth, and overall appearance of the coastline, seawater mixing in the bottom layer is weak, resulting in increased nutrients concentration, which in turn causes an unlimited growth of *T. basicrassa* sporophytes. In some sites of this bottom, it formed mono-species communities at 15-17 m deep.

Some kelp species have been reported to have narrow distribution (Petrov and Gussarova 1972, Petrov and Kusakin 1997, Lee and Yoon 1998, Kawai et al. 2008, Klochkova and Klochkova 2010). Other laminariacean algae have

discontinuous distributions and populations of the same species can be found at large distances. For example, *Arthrothamnus kurilensis* Ruprecht is mainly distributed on the Kurile Islands, but another isolated population exists on the south of Sakhalin Island on a small area of sea floor characterised by upwelling of cold bottom waters (called “Makarov’s spot” in Russian) (Klochko 1998). *Laminaria gurjanovae* Zinova also has discontinuous distribution on the Russian Far East. Thus, a small deep-water population of *T. basicrassa* near Nedorazumeniya Island also seemed like a relict population of once widespread species. Although all plants from this area became gigantic, the increase in size was accompanied by a significant decrease in the thickness of blade. Such changes occur in plants when they grow in seawater with low mobility and high nutrients concentration, because the lack of laminar flow, which is supposed to bring nutrients to the blade’s surface, is compensated by an increased absorbing surface area. For example, we observed very large plants of *Sacharina bongardiana* on the north-eastern Kamchatka in Yuzhnaya Glubokaya Bay in the exit site of underwater fumaroles (Klochko and Berezovskaya 1997). Gussarova (1975) reported on seaweed gigantism from the Kurile Islands due to the enrichment of coastal seawaters with volcanic ashes.

During hydrobiological expedition on the northern continental coast of the Sea of Okhotsk (Klochko et al. 2013) we confirmed that *T. basicrassa* does not have wide distribution in this area. It usually inhabits places with low level of hydrodynamics, at depths of 4-22 m, showing preference for the cold bottom layer (12-18 m deep). Its distribution border usually coincided with the replacement of hard substrates (i.e., rocks, boulders) with soft substrate (i.e., sand), and most commonly it inhabited sandy silted bottom with more or less frequent boulders, to which it attached. It did not grow in clusters of plants or forming dense covers on the bottoms, and the maximum number of plants per 1 square meter was 5-7. Under favorable conditions it formed mono-species communities with an average biomass of 7.5 kg m⁻².

A dwarf kelp, which is morphologically unassignable to any known species of laminariacean algae, was found on rocks and boulders at 4-7 m deep in the same locality. This dwarf laminariacean alga distributed sparsely in that area and never grew in groups (Klochko et al. 2013). During analysis of the underwater videos of seaweed beds from other areas of Tau Bay, we also found several more plants with same size and morphology. Although their morphol-

ogy was dramatically different from normal sporophytes of *T. basicrassa* our molecular data showed that the dwarf one is just a different life form of *T. basicrassa*. Comparative study of their karyotypes showed that this morphological variation is due to the difference in ploidy levels. Chromosome number of dwarf plants was half of that in the normal sporophytes of *T. basicrassa*. Although no reproductive structures were found on the collected materials, the dwarf thallus has probably derived parthenogenetically from unfertilized eggs of *T. basicrassa*.

In laboratory culture, unfertilized eggs of laminariacean algae are known to develop parthenogenetically, but those plants were usually shaped abnormal and died ephemerally (Ar Gall et al. 1996). Development of parthenosporophytes under laboratory conditions has been reported in many kelp species (Fang and Dai 1980, Lewis et al. 1993, Oppliger et al. 2007, Shan et al. 2013). In *Saccharina japonica* (Areschoug) Lane, Mayes, Druehl et Saunders, female parthenosporophytes developed zoospores, which grew into microscopic female gametophytes, produced eggs later, fused with male sperms of this species and developed into normal diploid sporophytes (Lewis et al. 1993). To the best of our knowledge, our results are the first example of parthenogenesis and / or apogamy in the laminariacean algae demonstrated to occur naturally in the field. It is noteworthy that the parthenosporophytes were at least 1 year old because they were overwintered plants. Further studies on the life history of *T. basicrassa* using laboratory culture may reveal the mechanisms that govern differential morphogenesis occurring in sporophytes and gametophytes of laminariacean algae.

This work was supported by a National Research Foundation of Korea Grant (NRF-2015M1A5A1041804) funded to GHK. This research was also supported by Golden Seed Project, Ministry of Agriculture, Food and Rural Affairs, and a grant from Marine Biotechnology Program (PJT200620, genome analysis of marine organisms and development of functional applications) funded by Ministry of Oceans and Fisheries, Korea. We thank Dr. Belij, M. N. (MagadanNIRO) for his help during samples collection from the Tau Bay. We thank Dr. Alejnikova, M. D. (Editorial board of “International Journal on Algae,” Algologia) for permission to reproduce picture of the holotype.
